**Abstract**

We evaluate the ability of market participants to anticipate monetary policy decisions in 14 countries. First, by looking at both magnitude and volatility of changes in the money market rates we show that the days of policy meetings are special days for financial markets. Second, we find that the predictability of FED, Bank of England and ECB is fully comparable. Finally, an econometric analysis of the ability of market participants to incorporate in the current short-term interest rates the expected policy changes shows that in the Euro area (and in other countries) policy decisions are anticipated well in advance.

*Key words:* Monetary policy, Predictability, Money market rates

## I. INTRODUCTION

The modern monetary policy literature has stressed the importance of a clear understanding of central bank's actions by financial markets in the formation of expectations about future interest rates developments. This is so because correct expectations help the central bank in its conduct of the monetary policy. While central banks only control short-term interest rates, economic theory indicates that longer-term interest rates and arbitrage conditions in financial markets matter the most for the transmission of monetary policy impulses to the economy. Longer-term interest rates, in turn, reflect expectations of future short-term rates and the credibility of the central bank. Hence, successful monetary policy is to a large extent a matter of shaping market expectations about the way in which short-term rates are likely to evolve not only in the period leading to the next policy decision but also later on.

Market participants' ability to predict future monetary policy decisions is often viewed as a direct consequence of the central bank's transparency.<sup>1</sup> A transparent overall monetary policy framework is therefore seen as highly desirable. This has come to be widely accepted by central bankers over the past decade. It is also widely acknowledged that a credible and predictable central bank can achieve its objective with smoother interest rate movements and at lower interest rate levels than a central bank with lower credibility.<sup>2</sup>

The economic literature has proposed several approaches to measure the predictability of central banks, ranging from survey and case-study approaches to statistical/econometric techniques (sometimes model-based) analyzing the development in the money market interest rates. However, given that perfect predictability may not be attainable, it should not be taken as the benchmark. In this respect, a cross country comparison offers a number of

---

<sup>1</sup> Woodford (2005) reviews general arguments for and against central-bank transparency, while Walsh (2007) analyses the optimal extent to which central banks should disseminate information to the private sector.

<sup>2</sup> Since the effectiveness of the monetary transmission mechanism depends heavily on the ability of monetary policy to affect the course of interest rates through financial market expectations, it is often argued that monetary policy should induce "rule like" behaviors on the part of market participants (see for instance Issing, 1999). This leads them to react to new developments in a manner consistent with the monetary policy strategy, thus aiding the smooth conduct of the monetary policy.

advantages, including the possibility to examine the central bank’s predictability across countries (and currency unions) with distinctive monetary policy frameworks and communication strategies. Trying to take advantage of this possibility, although the focus of the paper is on the performance of the ECB relative to that of the FED and the Bank of England, we examine the ability of financial markets to correctly anticipate policy decisions in 14 central banks -- from both industrialized and emerging market economies -- over a period of 5 years using the changes in 1-, 3- and 12-month money market rates on the days of monetary policy meetings.

The main results can be summarized as follows. First, a preliminary analysis of both the volatility and the magnitude of the changes in the money interest rates in the days of policy meetings suggests that the days in which the board of the central bank meets are special days. For each country, both the standard deviation and the average absolute money market interest rates change are significantly larger than in normal days. Second, according to two different measures of predictability the performance of the ECB is in line if not slightly better than that of the Bank of England and the FED. Finally, an econometric analysis of the ability of market participants to incorporate in the current interest rates the expected changes in the key policy rate shows that the ECB compares again very well in terms of predictability with the other central banks of the sample.

The paper is organized as follows. Section 2 provides an analysis of the relevance of the policy announcements by 14 central banks for the magnitude and the volatility of the money market interest rate changes; Section 3 proposes two different measures of predictability based on the money market behavior in the days of policy meetings; Section 4 compares the ability of financial markets in factoring into the short-term interest rates the expected changes in the key policy rate; Section 5 concludes.

**II. ARE POLICY MEETINGS’ DAYS DIFFERENT DAYS?**

In the paper we use data from 13 countries and 1 currency union: Australia, Canada, the Czech Republic, the Euro area, Hungary, New Zealand, Norway, Poland, South Africa,

Sweden, Switzerland, Thailand, the United Kingdom and the United States.<sup>3</sup> This enables us to investigate predictability in a relatively large set of central banks, all of them with a particular focus on ensuring price stability. The sample starts in 1999, when the single monetary policy of the ECB began.

Recently, several papers have investigated how well markets are able to anticipate the monetary policy by the Fed (Poole and Rasche; 2000, Kuttner; 2001, Demiralp and Jordà; 2004, Ehrman and Fratzscher; 2007a) and the ECB (Hartmann et al.; 2001, Gaspar et al.; 2001, Perez-Quiros and Sicilia; 2002, Bernoth and von Hagen; 2004), while Coppel and Connolly (2003) and Ehrman and Fratzscher (2007b) provided a cross-country comparison of some OECD economies. The main finding of this literature is that market participants in industrialized countries are nowadays better able to anticipate monetary policy decisions than in the 1980s or early 1990s. It seems plausible to assume that the improvement in predictability is at least in part related to the increased public availability of information about the monetary policy strategy and how decisions are taken. Previously, secrecy was the byword in central banking. Now, this trend has changed and there has been a clear progress towards increasing openness and transparency during the last decade. Along this line, Eiffinger and Geraats (2006) propose an index of transparency for a sample of industrialized economies based on a theory-consistent framework.

However, previous empirical research reveals that there is a variety of different techniques available to model predictability. Given our heterogeneous sample, a simple framework, which can be easily applied to all countries, would be highly desirable. A first intuitive approach to measure the extent to which market participants are surprised by a monetary policy decision is to compute the change in money market interest rates on the days of the policy meetings. That is, the value:

$$\delta_t = |i_t - i_{t-1}|,$$

where  $i_t$  is the market interest rate on the day of the meeting (using close of day data). The rationale behind using  $\delta$  as a measure of monetary policy predictability is as simple as the

---

<sup>3</sup> We do not consider Japan, because a strong deflationary pressure has forced the Bank of Japan to keep nominal interest rates close to the zero lower bound level since 1995.

following: the higher the degree to which the market anticipates the policy decision, the more muted the response in the short-term interest rates on the day of the announcement. Thus, not only the magnitude but also the standard deviation of the changes in the market interest rates to policy decisions can be compared among central banks. In fact, when a policy decision is correctly foreseen also the market volatility should not be influenced by the announcement.<sup>4</sup>

Which financial instrument should be used to measure the market response to policy announcements? In the literature a wide range of market instruments has been used to extract this information.<sup>5</sup> Every interest rate has its own advantages and disadvantages. In particular, the existence of several sources of bias, as term premia and differences in the liquidity, complicates the extraction of a “pure measure” of predictability, especially for very short-term rates. Furthermore, the availability of market instruments varies substantially across countries. In this paper, we calculate the market responses to the monetary policy decisions using money market rates at 1-, 3- and 12-month maturities. These rates were readily available for all the countries in the sample.<sup>6</sup>

Table A1 (in the Appendix) shows the standard deviation of the daily changes in the money market rates on the days when monetary policy meetings took place, between January 1999 and April 2004. The table also reports the standard deviation of all daily changes and distinguishes between announcements of decisions to alter the key interest rate and “no change” announcements.

Looking at the volatility in the 1-month market rates on the policy meeting days, it is possible to detect a strong heterogeneity across the 14 countries. However, a standard *F*-test shows that for each country, with the exception of Thailand in the 1-month market and Poland in the 12-month market, the null hypothesis of identical variances between “normal”

<sup>4</sup> While the analysis of short-term rates is mostly used in the literature, other approaches are also employed to assess the predictability of central banks. For instance, Sager and Taylor (2004) analyze the news effect of monetary policy disclosure by the ECB on the foreign exchange market, while Bomfim (2003) looks at the influence of FED announcements on the US stock market.

<sup>5</sup> See, for instance, Perez-Quiros and Sicilia (2002) for a discussion about the different instruments that can be employed for the Euro area and Cochrane and Piazzesi (2002) for an investigation on the relevance of the interest rate maturity for the relationship between FED funds target rates and market interest rates in the US.

<sup>6</sup> In a separate Annex we report the details about each country data.

days and days of policy meetings can be rejected at the 5% level of significance. This result suggests that even in the more mature economies of the sample the volatility in the money market on the days of policy meetings is larger than usual.<sup>7</sup> In addition, the market volatility around days of meetings seems to depend on the policy decision. The standard deviation of the changes in the money market rates when a modification in the official policy rate is decided is significantly larger than when the monetary policy authority does not change the official rate.<sup>8</sup>

A second, more direct, way of investigating whether the market behavior is different in meetings' days is to run a regression of the (absolute) changes in the money rates on a time dummy accounting for monetary policy meetings:

$$(1) \quad \delta_{jt} = c_j + \theta_j D_{jt} + \varepsilon_{jt} \quad j = 1, \dots, 14;$$

where  $c_j$  is a constant and  $D_{jt}$  is a dummy variable which takes the value of 1 in policy meetings' days and 0 elsewhere, for each country  $j$ .

It turns out that the dummy's coefficient  $\theta$  is always strongly significant all through the sample, thus supporting the idea that the days in which the board of the monetary policy authority meets are special days for financial markets also as concern the magnitude of the interest rate changes.

### III. PREDICTABILITY AROUND POLICY DECISIONS

#### The Hit-Rate

A first measure of central banks' predictability is here constructed by comparing the changes in the money market in the days of policy meetings to a benchmark. Changes in excess of the benchmark would signal a "surprise" and thus the failure of the market in

---

<sup>7</sup> For the Euro area, this result is consistent with the findings in Bernoth and von Hagen (2004), in which the authors analyze the Euribor future rates.

<sup>8</sup> According to the  $F$ -test, this result holds true for all countries and all maturities.

anticipating the central bank behavior. The “hit rate” is computed as the number of times (in per cent) the market was able to correctly anticipate the monetary policy decision.<sup>9</sup>

In order to set the benchmark, and thus to identify a surprise, we use two different measures: a) two times the standard deviation of all daily changes (regardless whether there was a policy meeting or not) and b) 12.5 basis points. Formally, for all countries, a monetary policy surprise is defined as:

$$(a) \quad \delta_k = |i_k - i_{k-1}| > 2\sigma_\delta$$

and/or

$$(b) \quad \delta_k = |i_k - i_{k-1}| > 0.0125$$

where  $k$  refers to the day of the selected meeting and  $\sigma_\delta$  is the standard deviation of the change in interest rates on all days of the sample.

Measure a) compares market rate changes around monetary policy decisions with the general behavior of the market. A change outside the selected “confidence bands” of two times the standard deviation is considered a significant deviation from the “normal” market rate volatility, thus we say that the market has been surprised by the central bank. Measure b), instead, is consistent with the idea that a standard monetary policy action is an increase or a decrease of *minimum* 25 basis points in the policy rate. Thus, a change of more than 12.5 basis points in the market rates on the day of a monetary policy meeting means that on the day immediately before the meeting less than 50% of the overall change was already factored into the market rates. This in turn suggests that market participants were surprised by the decision.<sup>10</sup>

Figures 1 to 3 depict the key interest rates of the ECB, the FED and the Bank of England and the development in the 1-month money market rates in each country.<sup>11</sup> The

<sup>9</sup> The use of the hit rate is common in the literature on monetary policy predictability: see for instance Gaspar et al. (2001), Ross (2002) and Coppel and Connolly (2003) for the setting of different benchmarks.

<sup>10</sup> Note that in the case of Hungary, Poland, South Africa and Thailand, where interest rate volatility is relatively high, the 12.5 b.p. benchmark turns out to be the strictest criterion, while the opposite is true for the rest of the panel.

<sup>11</sup> Hartmann et al. (2001) and Ewerhart et al. (2004) are extensive analyses of the microstructure of the Euro area money market, while broad analyses of the functioning of the interbank money market in the US are

white circles represent the meetings of the ECB's Governing Council, the FED's Federal Open Market Committee and the Bank of England Monetary Policy Committee in which the decision on the rate was "correctly" predicted by the market (according to the 12.5 basis points criterion), while the black circles are those dates in which a surprise arose, regardless of whether the decision was to change or not the policy rate. It is possible to see that for the Euro area the black circles are concentrated in the first part of the graph only (Figure 1). In particular, the last surprise by the Governing Council is dated 17 September 2001: it seems that since then the ECB has significantly improved its predictability.<sup>12</sup>

As for the FED, Figure 2 shows a particular feature of the US money market: the surprises in the 1-month rate concern only the days in which a change in the target for the federal funds rate was decided. All the decisions of a "no change" were correctly predicted. Finally, Figure 3 suggests that the financial markets in UK were more easily caught off guard when the MPC cut the official interest rate. It happened 6 times out of 13, a result in line with the findings of Ross (2002).

Table A2a and A2b (in the Appendix) report the hit rate for the 14 countries using the 1-, 3- and 12-month money market interest rates. The value of the hit rate is shown for both definitions of the benchmark. Furthermore, the tables distinguish between meetings in which the policy rate was changed and meetings in which the decision was not to change it. Before analyzing the data in detail, two general features might be noted. First, there is not a central bank which is the most predictable according to the two benchmarks and for all interest rate maturities. Second, confirming the results of the analysis of the volatility in Section 2, decisions of not changing the policy rate are generally better foreseen than decisions of changing the rate.

According to the ranking provided by the overall hit rate in the case of the 12.5 basis points criterion, the Euro area has the best score: financial markets were able to correctly

---

provided by Bartolini et al. (2002) and Demiralp and Farley (2005). For the US, in the attempt of modelling the daily behavior of the FED funds rate, Sarno et al. (2005) have analyzed the forecasting properties of several econometric specifications. In addition, Colarossi and Zaghini (2007) provided an analysis of the evolution over time of the linkages between money markets volatilities for the US and the Euro Area. For UK related works see Haldane and Read (2000) and Clare and Courtenay (2001).

<sup>12</sup> The "surprise" dates here identified are exactly the same Perez-Quiroz and Sicilia (2002) detected analyzing the jumps in the EONIA rate.

predict the outcome of the ECB policy meeting 94 times out of 100. The US and Australia follow closely with a hit rate of 91%, while the Bank of England performs slightly worse than the ECB and the FED with a value of the index of 84%.

The predictability of a “no change” decision is almost perfect in the Euro area, regardless of the market interest rate considered. Out of the 85 meetings in which the decision of the Governing Council was not to change the key interest rate, there were only two surprises as measured by the 1-month interest rate (and one surprise as measured by the 3-month and the 12-month rates).<sup>13</sup> Only Switzerland has a record of 100% “no change” decisions detected in advance in all the three interest rate maturities. The US follows closely with only one surprise in the 12-month rates.<sup>14</sup> However, both Switzerland and the US witnessed a much shorter number of meetings than the Euro area over the period under analysis (24 and 45, respectively, vs. 100). Also the UK perform fairly well with a hit rate of 91%. As for lower degrees of predictability, a value of the index below 90% in at least one of the market rates is recorded in both industrialized countries (Canada, New Zealand and Norway) and emerging economies (Poland, South Africa and Thailand).

When considering the meetings in which a decision to change the policy rate has been made, the hit rate drops significantly. Focusing again on the 1-month rates and the 12.5 basis points definition, the hit rate ranges from 24% in South Africa to 85% in Canada. In the Euro area 73% of the changes in the rate were correctly predicted by each market, i.e. 4 times out of 15 the market was surprised by the ECB’s decision to move the key rate. Comparing these results with those of other industrialized economies we can see that the Euro area hit rate is above those from New Zealand, Norway, Sweden, Switzerland and UK (ranging from 42% to 70%) and below those from Australia, Canada and the US (from 79% to 85%).

The ranking of the industrialized countries is almost unchanged also according to the definition of the hit rate based on 2 times the standard deviation (Table A2b). However, as expected, the degree of predictability increases strongly in those countries in which the

<sup>13</sup> This result is in line with the findings in Perez-Quiros and Sicilia (2002), which identify a hit rate of 94% when the two-week EONIA swap money market is used over the shorter period from 1 January 1999 to 7 June 2002.

<sup>14</sup> Predictability of 100% in at least one market is also recorded in Australia, Canada, the Czech Republic, Hungary, Sweden and the UK.

market volatility is larger (Hungary, Poland, South Africa and Thailand). As regards the general index, the Euro area performs slightly better than the US and the UK (87% vs. 80% and 73%, respectively).

### The money market adjustment

A second indicator of predictability is based on the estimated measure of the financial markets reaction to monetary policy moves. In particular, we regress the daily changes in the 1-month money market rate,  $\Delta i_{jt}$  for country  $j$ , on a constant,  $\alpha$ , and the changes in the key policy rate,  $\Delta p_{jt}$ :

$$(2) \quad \Delta i_{jt} = \alpha_j + \gamma_j \Delta p_{jt} + \varepsilon_{jt}.$$

The estimated coefficients on the policy changes are presented in Table 1.<sup>15</sup> The intuition behind this technique is analogous to the volatility/magnitude analysis performed in the previous sections. A low value of  $\gamma$  implies a small market response to the policy announcement, thus suggesting that the market was already pricing-in and thus anticipating the monetary policy decision.<sup>16</sup> The main difference is that equation (2) takes into account the differences in the average size of policy moves among central banks.

Except for South Africa and Thailand the  $\gamma$ -coefficient is of the expected sign and significant all through the sample.<sup>17</sup> In particular, Australia and Canada show the lowest coefficients, while Hungary and then the Czech Republic the highest. This suggests that the market participants in Australia and Canada are able to predict the outcome of the central banks policy decisions relatively well, with a response on the days of the policy change of

---

<sup>15</sup> This methodology was first introduced by Cook and Hahn (1989) to examine the one-day response of bond rates to changes in the target Fed funds rate.

<sup>16</sup> As expected, the constant is not significantly different from zero in any country. In addition, because the error term cannot be expected to be “white noise”, the Newey-West heteroskedasticity and autocorrelation-consistent standard errors of each coefficient are reported in the table.

<sup>17</sup> In the case of South Africa the coefficient is not significantly different from zero, while for Thailand it is not significant and negative, a result which is at odds with the theory. The reason is likely to be that the money market is not properly developed in these countries, as already suggested in the previous section by the large volatility recorded.

only 17% of the change in the key rate, while the opposite is true for the two Eastern European countries, responding by between 52% to 84% of the policy change.

Given the apparent large heterogeneity of the response to a monetary policy change we run a Wald test to check whether the differences in the  $\gamma$  coefficients are statistically significant across countries. In particular, we tested the null hypothesis that the value of  $\gamma$  for Canada is the same in the rest of the countries. The null hypothesis was not rejected for Australia and Norway (at the 1% level of significance). Thus suggesting that together with Canada the latter two countries perform very well in anticipating the monetary policy decision of the central bank. For the rest of the panel, the coefficients are significantly different at the 5% level, hinting to a lower degree of predictability (see the last column of Table 1).

In order to “rank” the ECB, using the same test, we also investigated whether the coefficient for the Euro area is statistically different from the one of the other countries. The null hypothesis of identical values cannot be rejected for Norway, New Zealand, US, UK and Switzerland at the 5% level, but is rejected for Australia and Canada (indicating that the ECB is less predictable) and for Sweden, Hungary, Poland and the Czech Republic (indicating that the ECB is more predictable). Thus the finding of a comparable degree of predictability among ECB, FED and Bank of England is again confirmed by equation (2).<sup>18</sup>

**IV. MARKET ANTICIPATION AND PASS-THROUGH OF MONETARY POLICY**

In this section we propose an econometric analysis of the relationship between the key policy rate and the money market rates over a longer period before the central bank’s meetings, in order asses how much in advance the market is able to price-in the expected monetary policy decision.

The results from regression (2), as well as all the analysis so far, rely exclusively on the information from market rates on the day of the monetary policy authority meeting and the day before. This may be in some instances insufficient, because we do not know when

<sup>18</sup> Note that for the US the value in Table 1 is the same Kuttner (2001) reports for the one-day changes in the 3-month US rate.

the market started pricing-in a change in the key rate. In fact, one runs the risk of concluding that market participants are perfectly anticipating a change in the official rate in situations in which the expectations are adjusted in a discrete way only one or two days before the policy meeting. This might happen if central bank officials, for instance via speeches or public statements, provide the public with an obvious hint about what they intend to do at the forthcoming meeting.

A way to control for this problem is to examine how much of the actual change is already priced-in by financial markets over the two weeks before the policy announcement. Following Coppel and Connolly (2003), we estimate the daily differences between the 1-month market interest rate  $i_{jt}$  and the key policy rate  $p_{jt}$  for country  $j$  as a function of a constant  $\beta_{0j}$ , and the change in the key policy rate  $\Delta p_{jt}$ , led by 1, 5 and 10 business days, and lagged by 5 business days:

$$(3) \quad i_{jt} - p_{jt} = \beta_{0j} + \beta_{1j}\Delta p_{jt+1} + \beta_{2j}\Delta p_{jt+5} + \beta_{3j}\Delta p_{jt+10} + \beta_{4j}\Delta p_{jt-5} + \varepsilon_{jt}.$$

The coefficients  $\beta_{1j}$ ,  $\beta_{2j}$  and  $\beta_{3j}$  can be interpreted as estimates of the degree to which the market has already priced-in the policy change one day, one week and two weeks ahead of the meeting, respectively. A value of zero would indicate that changes in the rate were generally unexpected by the market at those dates. On the contrary, a large value of the coefficients would suggest that the market was able to correctly anticipate (well in advance) the decisions to change the key interest rates. However, while  $\beta_{1j}$  can be directly taken as the share of the policy change that was anticipated by market participants one day before the meeting,  $\beta_{2j}$  and  $\beta_{3j}$  should be interpreted more cautiously. In fact, the one month interest rate reflects the expected average interest rate over the coming month and thus includes expectations of an unchanged key rate prior to the policy meeting and a different rate (lower or higher) afterwards. Finally, the coefficient  $\beta_{4j}$  can be interpreted as a measure of the pass-through of the key policy rate to market rates within a week after the move. A value close to zero would indicate that the changes in policy rates are fully passed-through in the 1-month money market rates in 5 business days.

In Table 2 we report the estimated values of the coefficients from equation (3) and the Newey-West heteroskedasticity and autocorrelation-consistent standard errors for the whole

set of countries under analysis. The standard tests suggest that while the 1-day anticipation coefficient is highly significant in each of the 14 countries, the 5-day coefficient is less significant in Hungary and South Africa (5% and 10%, respectively) and it is not significant in Poland. At the same time, the 10-day coefficient is only weakly or non-significant in all the emerging market economies and in Switzerland. Excluding the countries where at least one of the policy anticipation coefficients is not significant, the table show that  $\beta_{1j}$ ,  $\beta_{2j}$  and  $\beta_{3j}$  are relatively similar across the panel. They are the highest in Australia and Canada, and the lowest in Hungary. As expected, they are decreasing with respect to distance of the policy meeting, i.e.  $\beta_{1j} > \beta_{2j} > \beta_{3j}$ , suggesting that the closer the meeting, the larger the degree of pricing-in by the market.

As for the lag-indicators, Table 2 suggests that while the policy moves have generally been fully passed-through within a week, there are some significant  $\beta_{4j}$  coefficients. A positive coefficient as in Australia, Canada, New Zealand and the US might suggests that market participants started to price-in well in advance the policy decision of the following month.

Concluding, it can be stated, with all the caution that is needed when directly comparing regression coefficients, that the degree of policy moves anticipation in the Euro area is around the average of industrialized economies and in line with central banks with a longer history such as the FED and the Bank of England.

V. CONCLUSION

Historically, for a variety of reasons, central banks have chosen different ways of communicating with the public and have relied on different instruments to be transparent. In addition, in the economic literature there are different views about the optimal degree of transparency. In some papers, like Eijffinger and Geraats (2006) and Gross (2002), transparency is identified with the amount and/or the degree of precision of information that central banks release to the public. According to other views, what is important, instead, is that the central bank provides the public with a clear understanding of the framework of the analysis and the procedures that the monetary authority follows in deciding what to do. The best way to communicate this to the public is by offering an explanation of the decisions that

have been already made. It follows that openness, and thus the release of information, is desirable only to the extent to which it enhances the understanding of the central bank behavior.<sup>19</sup>

However, over the past decade, it has come to be widely accepted that transparency in monetary policy making is highly desirable, since the effectiveness of monetary impulses improves when financial markets understand how the central bank conducts the monetary policy and why decisions are taken. In particular, better information by market participants about central bank actions and intentions increases the degree to which monetary authorities can actually affect market's expectations about future changes in the official rate and thus about long-term interest rates. This paper has examined the predictability, i.e. the ability of financial markets in anticipating monetary policy decisions, of 14 different central banks with various monetary policy frameworks and different ways of communicating to the public.

As in any cross-country analysis, it should be born in mind that several caveats are associated with this kind of direct comparison. In particular, the properties of the financial instruments used to evaluate market expectations about future policy decisions may vary across countries. Different types of liquidity, term and risk premia may affect the findings obtained in the exercises performed in this study. Another factor, which is worth mentioning, is the evolution in the macroeconomic environment occurred in the period under review. A large part of the overall increase in predictability in some countries over the last decade has probably been due to a lower general level of interest rates, as inflation levels have fallen, and greater macroeconomic stability has been achieved. This makes it difficult to isolate with precision the contribution of the increased transparency in central banks behavior in reducing the volatility in short-term rates. Finally, a third caveat concerns the span of our time sample, which, in order to include the Euro area, is relatively short. However, even if the analysis of the money market dynamics started in January 1999, the number of policy meetings and interest rates changes were large enough for the standard statistical exercises to be performed.

---

<sup>19</sup> See Winkler (2000), Woodford (2003 and 2005) and Thornton (2003) among others.

Using money market rates at different maturities we reached two results. First, by comparing measures of the magnitude and the volatility of the changes in the money markets rates in the days of the policy meetings, we showed that the days in which policy decisions are taken are special days for financial markets. Second, according to two different measures of predictability and via an assessment of the ability of financial agents in incorporating well in advance the policy decisions into market rates, we showed that the overall predictability of the ECB is in line with that of our two “benchmarks”: the FED and the Bank of England.

Our findings fit well with other recent contributions, especially about the Euro area. In fact our results are fully consistent with works employing somewhat different kinds of analysis and relying on different measures of predictability such as the studies by Perez-Quiros and Sicilia (2002) and Bernoth and von Hagen (2004). In addition, also the international ranking of the ECB with respect to other central banks and in particular the comparison with the FED and the Bank of England is confirmed by several sources (Ross, 2002; Coppel and Connolly, 2003).

Future extensions of the work may point to assess whether some specific characteristics of the monetary policy and communication strategy of a central bank have influence on its predictability. For instance, while all the countries in our sample have the price stability as central part of their policy objective, the ECB, the Swiss National Bank and the FED are the only central banks without a formal inflation target. A possible exercise could evaluate whether inflation target countries are more predictable than others. In addition, also other modalities of the policy framework like the publication of the minutes of the meetings and the voting record may be assessed.
